Designing an RD53B Trigger Pattern Encoder for the YARR Readout System

Lucas Cendes

Agenda

- Background
 - Large Hadron Collider (LHC)
 - RD53B Readout Chip
 - YARR
- Design
 - Trigger Code Generator
 - Trigger Extender
- Testing
 - Testbench design
 - Simulation Results
 - YARR scans on real hardware

Large Hadron Collider (LHC)

- Largest and most powerful particle accelerator in the world
- Collisions are produced by two particle beams travelling in opposite directions
 - Beams produced by several intense bunches of protons
 - Bunch crossing occurs when two beams cross
 - This happens at a rate of 40 MHz
- One of the main components of the LHC is the ATLAS detector
 - Designed to detect the smallest and most energetic particles
 - The Pixel Detector is one of the main components of the ATLAS detector

High-Luminosity Upgrade (HL-LHC)

- Intends to increase the luminosity by a factor of 10 times
 - This will result in a higher frequency of collisions
 - It will also allow the LHC experiments to observe rare physical processes
- The luminosity will be up to seven times greater than what the ATLAS detector was designed for
 - This will require new detectors to be developed and installed
 - $\circ \qquad {\sf New \, readout \, chips \, will \, have \, to \, be \, developed}$

RD53B Readout Chip

- The RD53B was designed to supersede the RD53A
 - The architecture of the RD53B was designed to be suitable for production
 - The chip also includes additional technology that facilitates its integration into the Pixel Detector
- Availability of the RD53B is currently limited
 - As a result of this, the ACME lab at UW developed an emulator for the chip
 - This will facilitate the process of testing and modifying the architecture of the chip
 - The two main components of the emulator are the TTC data processing block and the Command Processor

RD53B Command Protocol

- Commands are sent as a continuous stream of serial data
- Each command is a 16-bit frame composed of two 8-bit symbols
- Commands can span multiple frames
- The command frames are DC-balanced
 - This means that every command is composed of eight 0's and eight 1's
 - This allows for clock recovery and error detection

Control Commands

- PLL_Lock (Idle) Command
 - Alternating series of 1's and 0's
 - Simulates a clock signal
 - Used to ensure that the RD53B input circuitry is locked to the correct clock
 - Also used as an idle command
- Sync Command
 - Used to determine the proper frame boundaries
 - Must be sent at the start of operation
 - Cannot be produced by any combination of command words

Trigger Commands

- Used to tell the RD53B chip to sample data from a specific bunch crossing
- Composed of an 8-bit trigger encoding and and 8-bit tag
- Trigger encodings determine which bunch crossing should be samples
 - Each 8-bit symbol is mapped to a 4-bit trigger patterns
 - The presence of a trigger indicates that the data from the respective bunch crossing should be sampled
- Tags are used to identify the specific sequence of bunch crossing that correspond to a command
 - There are a total of 54 8-bit tags
 - Each tag is mapped to a 6-bit tag base

Trigger Pattern	Binary encoding	Hexadecimal Encoding
T000	0010_1011	0x2B
00T0	0010_1101	0x2D

YARR

PCIe bus

YARR Software

Host Computer

- Data acquisition system designed for readout chips in the pixel detector
- Converts trigger patterns into the proper command encoding
- Also analyses the data produced by the chip

YARR

PCIe bus

YARR

Software

Host Computer

Composed of a software and a hardware part

- Software part is responsible for most of the data processing
- Hardware part sends commands to the chip and sends the data received from the chip to the host computer

YARR Firmware TX Core

- The TX core is responsible for sending commands to the readout chip
- It is currently composed of a trigger unit and a TX channel
- It hosts a series of registers that can be configured through a Wishbone bus
- The TX core is currently being updated to support the command protocol of the RD53B chip
 - This requires the development of a trigger pattern encoder
 - The development of this module is the main focus of this project

Trigger Code Generator

Trigger Pulse Processing

- Each Trigger Pulse lasts for 4 clock cycles
- A trigger is detected if the input port is set to 1 at any of the 4 clock cycles
- Trigger bits are generated through the usage of a 4-bit trigger pulse shift register and a 2-bit trigger counter
 - A bit is shifted into the shift register at each clock cycle
 - When the trigger counter back to 0, all bits in the shift register are OR'ed and a new trigger bit is produced

Trigger Command Generation

- The module keeps track of a 4-bit trigger pattern shift register and a 2-bit command counter
- When the trigger counter is set to 3, a new trigger bit is shifted into the trigger pattern shift register and the command counter is incremented
- When the command counter rolls back to 0, the trigger pattern is encoded into a 8-bit trigger encoding

Tag Generation

- A 6-bit counter keeps track of the tag base
- The counter rolls back to 0 whenever it is incremented past a value of 49
- Whenever a new trigger encoding is ready, the value of the counter tag is encoded into a 8-bit tag encoding
- The counter is incremented whenever a new command word is produced

Command Word Transmission

A new command word is produced every 16

clock cycles

If no triggers were detected in that interval, the command word is set to the idle command

Enable

Otherwise, the command word is set to the concatenation of the 8-bit trigger encoding and the 8-bit tag encoding

The output is updated every 32 clock cycles

The first word produced in that interval is stored at the first word register

The next word is concatenated to the first word the resulting 32-bit value is outputted

The first word done signal is asserted if the module is enabled and if there is at least one non-idle command word being outputted

Trigger Extender

- Allows the YARR software to extend the duration of a trigger pulse
- Module functions as a pass-through if the extension interval is set to 0
- Otherwise, any trigger pulses received by the trigger extender will be extender by the given number of clock cycles

Modifications to Existing Code

- Two new configurations registers were added to the TX core:
 - Trigger Extension Interval (Wishbone address 0x20)
 - Trigger Code Generator Enable (Wishbone address 0x21)
- The command words outputted by the trigger code generator were mapped to the highest priority of the priority encoder in the TX channel

Simulation Testbench Design

- The YARR firmware was connected to the RD53B emulator
- A counter was used to synchronize the trigger pulses with the code production intervals of the trigger code generator.
- The necessary TX core configuration registers were configured at the start of the simulation
- The trigger patterns 1000, 0001, 0000, 1001 were simulated
- Trigger extension intervals of 7, 11 and 15 were tested with the 1000 trigger pattern

YARR Scans in Real Hardware

- This test was used to check if the modifications done to the YARR do not interfere with the existing functionality
- The scans inject 100 digital pulses into each pixel of the RD53B chip
- The modified YARR firmware was loaded into a Trenz Electronic TEF1001 FPGA board
- The board was connected to the PCIe port of a computer
- The output port of the board was connected to the CMD/DATA port of a real RD53B chip
- The scans were then run from the computer connected to the Trenz Electronic TEF1001 board and a occupancy map was produced
